

### Accuracy and precision:

**Accuracy** refers to closeness of the measurements to a specific value, while **precision** refers to the closeness of the measurements to each other. Also called repeatability.

Let's consider this example:

a servo motor is connected to a lead screw through a planetary gear. The load is connected to a secondary linear encoder.

Motor encoder resolution : 10,000 PPR

Linear encoder resolution : 1 $\mu$ m (one micron)

Gear ratio: 1:10

Gear backlash: 10 arc min

Lead screw pitch: 10mm

Lead screw backlash: 1 $\mu$ m

Let's calculate the **accuracy** of the system:

If we assume a rigid system (no backlash) then the minimal possible step will be:

$$\frac{[10\text{mm (pitch)}]}{[10,000 \text{ revolution (moto encoder)}]} \div [10 \text{ (gear)}] = 0.0000001\text{m} = 0.1\mu\text{m}.$$

Since our linear encoder is 1 $\mu$ m, our position loop will give us a 1 $\mu$ m resolution .

\* assuming ideal encoder

The motor encoder is recommended to have at list a X10 better resolution than the reflected load encoder!

Now for the **precision**:

$$[1\mu\text{m}(\text{leadscrew})] + [10\text{mm}(\text{screw pitch}) / (21,600\text{arc minutes in gear cycle}) * 10\text{arc min}(\text{gear})]=$$

$1\mu\text{m} + 4.6\mu\text{m} = 5.6\mu\text{m}$  is the maximal mechanical error.

In this example the linear encoder will allow us to correct the errors and bring precision to  $1\mu\text{m}$ .
